### 1) Shortest Job First (SJF)

#### Explanation of scheduling scheme

This is a non-preemptive scheduling algorithm that runs the shortest process in CPU ready queue until the process goes to wait or is terminated state. The processes in this case have numerous CPU and IO burst cycles. The process with the smallest CPU burst time in ready queue is performed after a running job enters the waiting state for I/O or is terminated.

Processes are executed sequentially in I/O. We have used an queue for I/O to store the processes waiting. This follows the first come first serve scheme. After a process finishes its CPU burst cycle, it goes into the IO queue if there is any I/O. Whenever a process's IO burst ends, it goes back to the ready queue if it still has to run. We sorted the array of process in ready queue on basis of current CPU burst time and took the first process to run.

To run this scheduler execute: make sjf

**Note:** To change input file kindly make appropriate changes in Makefile.

#### The expected job characteristics of this scheme are the following:

- Average waiting time of a process is reduced.
- Average turnaround time of a process is reduced.
- Shorter jobs that arrive after longer jobs have a greater waiting time and completion time since they execute after the lengthy job gets completed.

#### Test process data for when the Shortest Job First scheme is suitable:

```
<html>
<body>
<pre>
0 3 2 1 -1
2 20 3 1 -1
3 1 -1
</pre></body></html>
```

Here, the processes with short CPU bursts execute first which reduces the average waiting time and turn around time. Here job 3 executes first than job 2 reducing the turn around time.

**Test process data for when the Shortest Job First scheme is not favorable or has shortcomings:**

```
<html>
<body>
<pre>
0 200 -1
1 1 1 3 -1
2 5 1 2 -1
5 3 -1

</pre></body></html>
```

The initial process arrives at time 0 in this case. It is a lengthy task, with the initial CPU burst lasting 200 seconds. It executes first, consuming the CPU and preventing the execution of shorter jobs that come just a few seconds later.

## 2) Shortest Remaining Time First (SRTF)

### Explanation of scheduling scheme

This is a preemptive scheduling algorithm that executes the process with the least amount of time remaining first among all the processes in the ready queue. If a job with a shorter remaining time comes while a job is running on the CPU, the existing job is preempted and this task begins running. The preempted is added back to the ready queue. In this case, the I/O device runs processes in the same order as in the previous scheduling scheme. An IO queue that follows the FCFS (first come, first served) scheme has been built, and the CPU ready queue is sorted every time to get the work with the least amount of time remaining to perform.

To run this scheduler execute: make srtf

**Note:** To change input file kindly make appropriate changes in Makefile.

**The expected job characteristics of this scheme are the following:**

- The average turnaround time is reduced.
- Compared to Shortest Job First, context switches are more.
- Throughput is increased.
- May result in starvation for long jobs if only short jobs keep coming in.

### **Test process data for when the Shortest Remaining Time First scheme is suitable:**

```
<html>
<body>
<pre>
0 2 3 2 -1
0 10 2 3 -1
2 1 1 2 -1
</pre></body></html>
```

The processes in this case are all small jobs that run fast, increasing throughput. In addition, we can see that the average turnaround time is less.

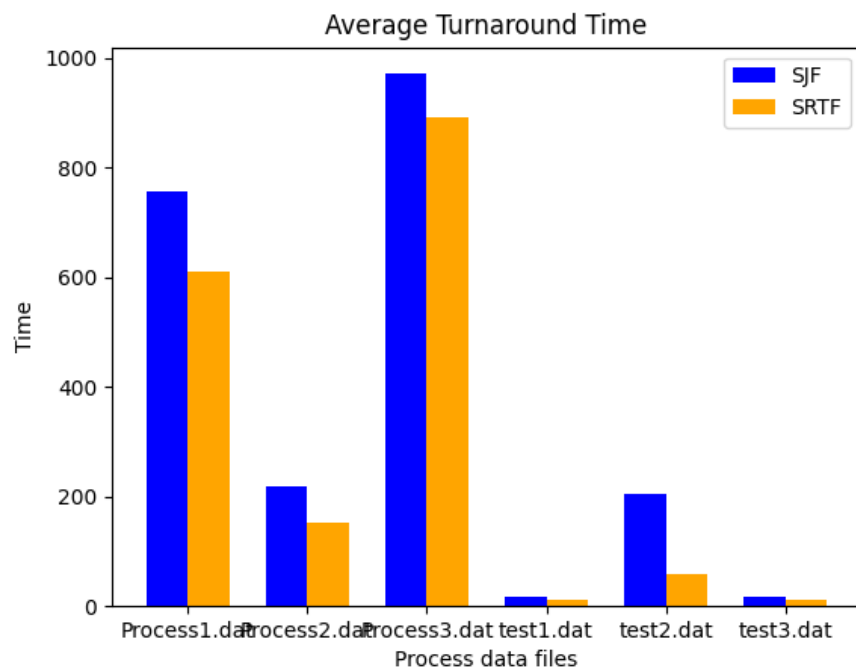

### **Test process data for when the Shortest Remaining Time First scheme is not favorable or has shortcomings:**

```
<html>
<body>
<pre>
0 4 2 3 -1
1 300 4 3 -1
2 1 -1
3 4 3 1 -1
3 1 -1
</pre></body></html>
```

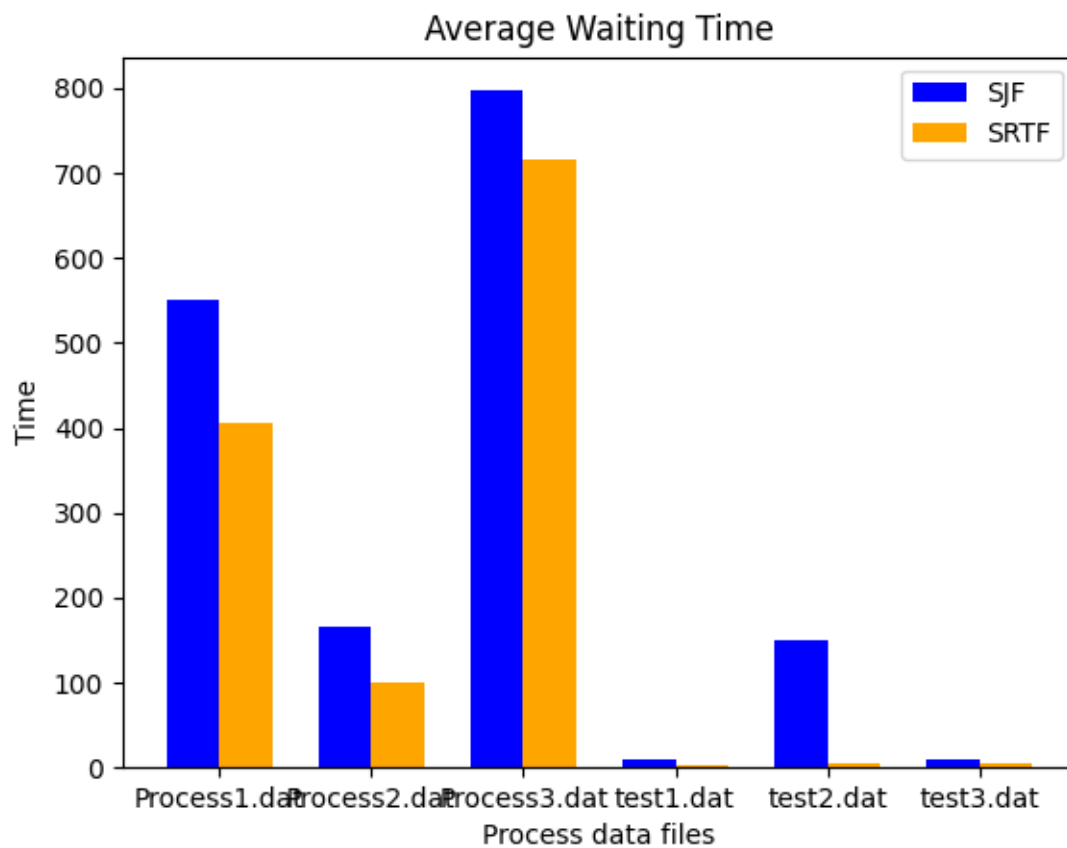

The lengthy task, which comes in after the short ones, is finished last since it always has more time left than the short jobs do. So, the Waiting times and average turnaround times are impacted.
